1 Abstract

This report presents a comprehensive time series analysis of atmospheric CO2 trends, focusing on the effectiveness of forecasting models trained on historical data from Mauna Loa Observatory. Using polynomial and seasonal ARIMA models, we assessed long-term trends and seasonal patterns in CO2 concentrations from 1959 onward. Based on data up to 1997, initial models were compared against current observations to identify gaps and refine forecasting accuracy. Updated models, incorporating seasonal adjustments and differencing techniques, demonstrated marked improvements, reducing forecast RSME and MAE by over 88%, thereby aligning more closely with observed data. Forecasts indicate that CO2 levels could exceed 500 ppmv by mid-century, underscoring an accelerated trajectory with significant environmental implications. This analysis highlights the need for adaptable models that account for evolving emissions patterns and policy impacts, offering a robust foundation for future climate forecasting efforts.

2 Introduction

Climate change remains an urgent issue as global temperatures rise, posing challenges for scientists and policymakers. Understanding the relationship between rising carbon dioxide (CO2) levels and global warming is essential to assess the long-term impact of human activities and inform effective policy decisions. This report presents forecasts of atmospheric CO2 concentration trends, focusing on evaluating the accuracy and adaptability of predictive models over time.

Geochemist Dr. Charles David Keeling's pioneering work in atmospheric CO2 measurements fundamentally shaped our understanding of the global carbon cycle. In 1958, Keeling's observations at the Mauna Loa Observatory produced the iconic "Keeling Curve," (Keeling 1960) which revealed a persistent rise in CO2 levels driven by fossil fuel combustion—a discovery with profound environmental and political implications. As CO2 is a greenhouse gas that traps heat in the atmosphere, rising concentrations contribute significantly to global temperature increases, disrupting ecosystems and causing sea level rise.

In re-examining Keeling's original findings from a present-day perspective, this study seeks to determine whether discrepancies between early forecasts and current observations reflect inherent model limitations or shifts within the CO2-generating system. Data collection methods had evolved significantly since 1997 when CO2 concentrations were measured monthly using a chemical gas analyzer based on infrared absorption. Today, a newer Cavity Ring-Down Spectroscopy (CRDS) system at Mauna Loa enhances measurement precision by determining CO2 concentrations based on absorption rates within an optical cavity, independent of light intensity or sample path length. This modern approach, which enables hourly measurements and heightened sample reliability, provides a more robust dataset to evaluate and refine model predictions.

This report assesses both short—and long-term predictive capabilities through a comparative analysis of polynomial and seasonal ARIMA models. It identifies areas where model adjustments improve forecast accuracy and uncovers patterns in CO2 trends that inform future climate impact assessments.

3 1997 Point of View CO2 Emission Analysis

3.1 Data

The current data is gathered from measurements made under Dr. Charles Keeling's study at the Mauna Loa Observatory in Hawaii (Cleaveland, 1993) and part of the R object co2. Measurements were taken by a chemical gas analyzer sensor, with detections based on infrared absorption. This data measures monthly CO2 concentration levels from January 1959 to December 1997. Units are in parts per million of CO2 (abbreviated as ppmv) using the SIO manometric mole fraction scale. Dr. Keeling initially designed a device to detect CO2 emitted from limestone near bodies of water. However, his measurements revealed a pattern of increasing CO2 concentrations at the global scale, urging further need to continue tracking the gas (Keeling, 1998). The time series shows a clear upward trend of global CO2 concentrations from 1959 to 1998, with an average increase of 1.26 CO2 ppmv and a standard deviation of .51 CO2 ppmv. Upon inspection of the yearly increases, the bulk of changing CO2 levels are between 0.75 and 2.0 CO2 ppmv.

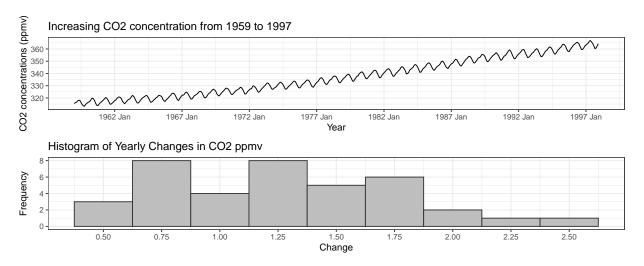

Figure 1: Data source: CO2 measurements from Mauna Loa Observatory

The time series also shows strong evidence of seasonality corresponding closely with the meteorological seasons of Autumn, Winter, Spring, and Summer. To gain further clarity on seasonality, we now look at the ACF plot and average CO2 concentration for each month.

We see a wave-shaped pattern among correlations between the current value and growing lags. Clearer evidence of seasonality is shown when inspecting the monthly average of the CO2 ppmv when averaged across all years in the available data. CO2 concentration peaks at the start of summer, and drops to a low in the fall, before rising again. This is likely due to the organic decomposition of plant life in these seasons (Keeling, 1960).

We now study the time series' stationarity. We first conduct the Augmented Dickey-Fuller (ADF) Test to test the null hypothesis that the time series is not stationary. As seen in the time series plot, we have a clear upward trend, suggesting non-stationarity. This is confirmed by a p-value of 0.2269 yielded by the ADF test, which indicates insufficient evidence to reject the null hypothesis of non-stationarity. To look at stationarity in variance, we fit a yearly CO2 average on the monthly time series and inspect the residuals from year to year. Although there are slight changes in the variance, they seem to regress to a constant variance over time. Thus, once we account for the yearly increases in CO2 ppmv, there is likely a constant variance over time.

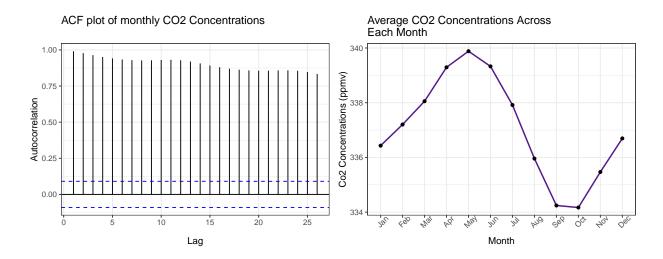

Figure 2: Observing seasonality in CO2 concentration

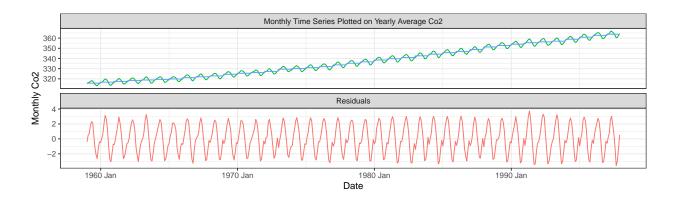

Figure 3: Studying variance over time

3.2 Linear time trend model

We now fit a linear time trend model to the co2 series and examine the characteristics of the fit and residuals.

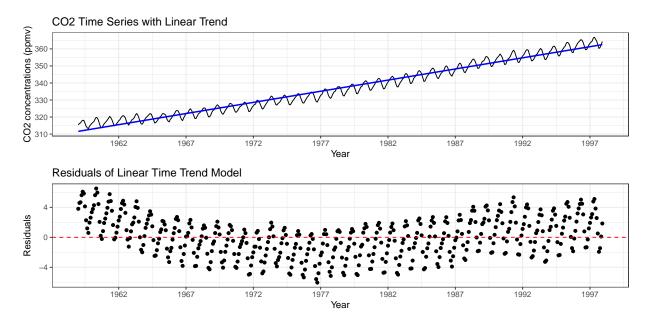

Figure 4: Evaluating a Linear Model

Upon inspection of linear fit, the fitted line appears to be systematically overestimating values at specific points and underestimating values at other points. This indicates that perhaps a higher-order polynomial might produce a better fit of the overall trend. The residuals of the linear model also exhibit a cyclical, non-linear pattern, indicating that the model does not capture the seasonality in the data. The curve also suggests that the linear model insufficiently captures the trend. We now assess a quadratic model to see if it better captures the data.

3.3 Quadratic time trend model

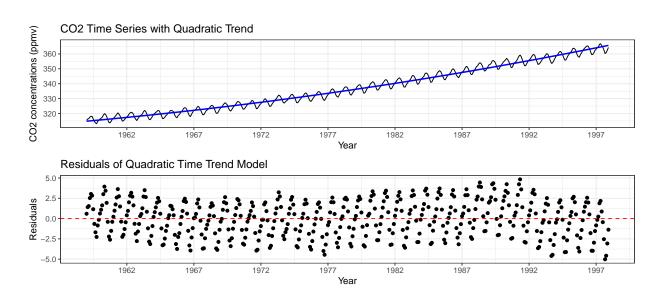

Figure 5: Evaluating a Quadratic Model

The quadratic model's residuals indicate a slight reduction in variance, demonstrating a slightly improved fit. However, the cyclical behavior remains, indicating that seasonality is still unaccounted for in the model. The residuals also have an overall non-random trend, indicating that the model may not capture all the structural details. We now fit a polynomial model to the data to see if there is an improved fit.

3.4 Polynomial Model

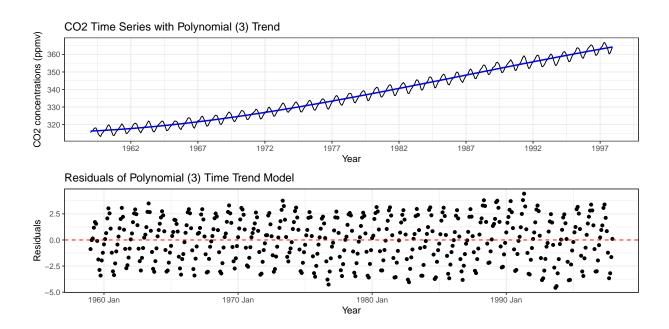

Figure 6: Evaluating a Polynomial (3) Model

The third-order polynomial model demonstrates improved residual behavior compared to quadratic and linear models, although it still does not capture the seasonality. We chose to stop at this order to prevent overfitting, as higher-order polynomials showed diminishing returns in model performance.

Apart from transforming the orders of the model, we were interested in data transformations - specifically logarithmic. As such, we experimented with a logarithmic dataset to observe the pattern of the data values.

3.4.1 Log Transformed Data

The logarithmic transformation reduces variance but offers minimal improvement compared to traditional plotting. This limited impact is likely due to the cyclical nature of the time series, which the transformation does not adequately address. Furthermore, as discussed, the variance of the time series looks about constant over time, indicating that a logarithmic transformation may be unnecessary.

3.4.2 Polynomial Regression Model Using Monthly Variation

To address the cyclical behavior, we develop another polynomial (degrees = 3) model that includes each month as a variable, since the average monthly CO2 emissions indicate significant cyclic patterns at the monthly level. By incorporating this variable we anticipate an improvement in the fit of our time series model. We get the plots below.

As seen above, incorporating the month dummy variable further reduced the range of residuals; they now range between 1 and -1. However, the residuals continue to display a seasonal pattern. To further refine the model, we chose to group the months into quarters to represent the seasons as the categorical variable season.

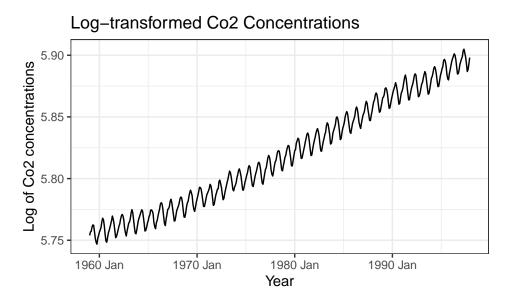

Figure 7: Evaluating effect of taking a log on the series

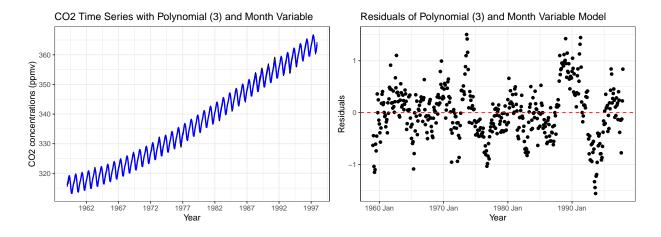

Figure 8: Evaluating a Polynomial (3) with month variable model

3.4.3 Polynomial Regression Model Using Seasonal Variation

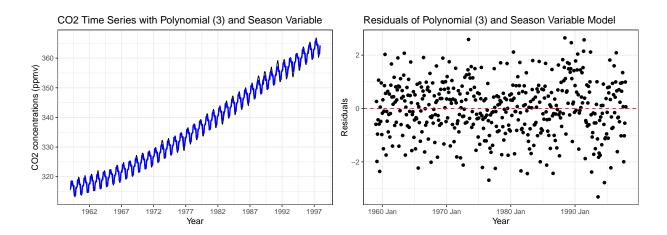

Figure 9: Evaluating a Polynomial (3) with season variable model

Incorporating the season variable yielded residuals randomly distributed around zero, as indicated by the red line. While the residual fluctuations expanded to a range of approximately [-2, 2], the random distribution supports the assumption of model adequacy. Therefore, we accept the model residuals and will forecast CO2 emissions through 2020 based on this model.

3.5 Polynomial CO2 Emissions Forecast Model to 2020

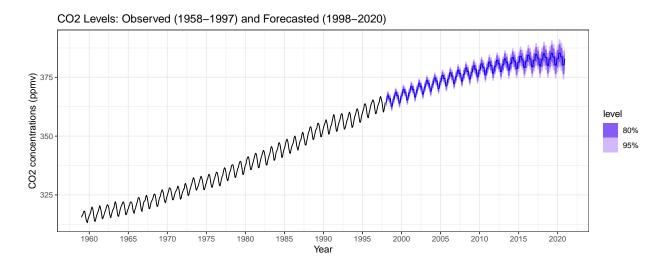

Figure 10: Forecasting CO2 levels up to 2020 using a Polynomial (3) with season variable model

The forecast model using the season variable demonstrates reasonable accuracy, projecting a continued upward trend with a gradual tapering effect through 2020, alongside persistent annual seasonality. This tapering is an inherent assumption of the third-degree polynomial model, though it may not be entirely warranted. Next, we will explore an ARIMA model to assess whether it captures the underlying patterns of the time series more effectively.

3.6 ARIMA times series model

Our exploratory data analysis indicated non-stationarity in the data. To address this, we will difference the series first at lag 1, then at lag 12 to account for seasonality over a year—an essential step to ensure stationarity before fitting the ARIMA model. We now examine the differenced time series.

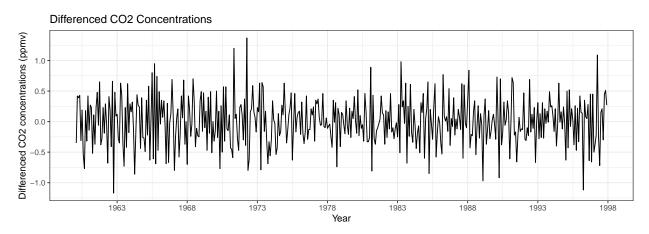

Figure 11: Differenced series looks more stationary in the mean and variance

The differenced time series plot appears more stationary in both mean and variance. This is supported by the Augmented Dickey-Fuller Test, which yields a p-value of 0.01, providing sufficient evidence to reject the null hypothesis of non-stationarity. We will now examine the ACF and PACF plots of the differenced series to guide the construction of our ARIMA model.

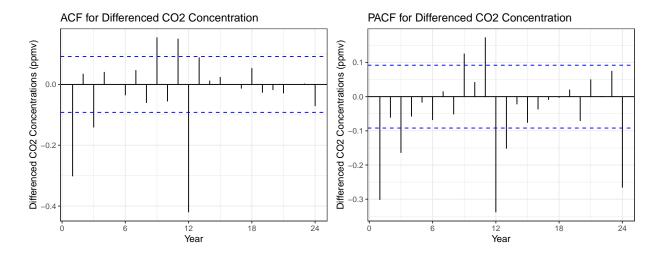

Figure 12: Evaluating ACF and PACF for differenced series

The ACF and PACF plots display strong autocorrelation at lag 1, with the ACF sharply cutting off after lag 1 and the PACF showing a significant spike at lag 1 followed by a gradual tapering. This pattern suggests the presence of an MA(1) component in our model. The spike at lag 12 in the ACF may also indicate a seasonal MA component.

The ARIMA function performed as expected, returning an ARIMA(0,1,1)(0,1,1)[12] function with a BIC of 182.32. We will now examine at the residuals for this model.

The residuals appear random, with no significant autocorrelations in the ACF and a close alignment to

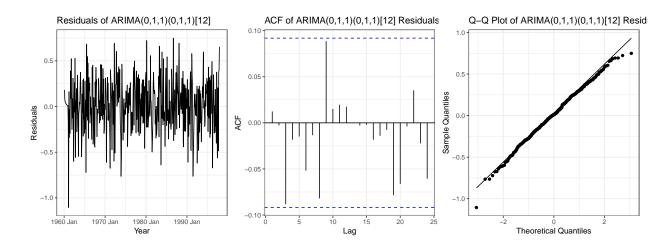

Figure 13: Evaluating ARIMA(0,1,1)(0,1,1)[12] model

normality in the Q-Q plot, indicating that the model effectively captures the underlying structure of the time series. The Ljung-Box test yielded a p-value of 0.6733, confirming insufficient evidence to reject the null hypothesis of no autocorrelation. We can now proceed with forecasting the time series through 2022, noting that the model does not predict any tapering of the overall trend.

3.7 ARIMA CO2 Emissions Forecast Model to 2022

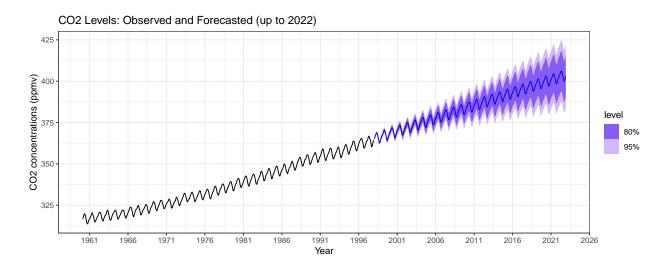

Figure 14: Forecasting up to 2022 using an ARIMA(0,1,1)(0,1,1)[12] model

The forecast for CO2 levels up to 2022 indicates a steady upward trend, continuing the trend of increasing concentrations. The model projects CO2 levels reaching approximately 415–425 ppmv by 2022, with seasonal fluctuations preserved throughout. The shaded regions represent confidence intervals, with the darker band showing the 80% confidence interval and the lighter band indicating the 95% confidence interval. These intervals suggest a high confidence in the continued rise, with little indication of tapering, consistent with ongoing emission patterns.

3.8 Forecasting Atmospheric CO2 growth

We forecast the timelines for atmospheric CO2 to reach 420 ppmv and ultimately reach 500 ppmv for both the initial and final occurrences. These benchmarks are significant: 420 ppmv marks a level associated with accelerated warming and potential climate tipping points, positioned as the midpoint between preindustrial levels (around 278 ppmv) and a doubling of that figure (556 ppmv). In contrast, 500 ppmv is a critical threshold beyond which severe, potentially irreversible impacts—such as extreme weather events and ecosystem disruptions—are anticipated. The forecasted timelines are summarized in the table below.

Table 1: CO2 Levels and Forecasted Times with 80% Confidence Intervals

CO2.Level	First.Month	First.Value	Last.Month	Last.Value
420 ppmv	2031 May	420.1 (402.3, 438.0)	2035 Oct	420.4 (399.5, 441.3)
500 ppmv	2083 Apr	500.4 (437.9, 562.9)	2085 Dec	500.9 (435.7, 566.2)

Our model also projects CO2 levels for the year 2100. While these forecasts include a standard deviation, they do not account for current efforts to reduce global greenhouse gases, such as the shift toward electric vehicles over gasoline-powered ones. As such, these projections, being highly dependent on human activities, may lack complete reliability without incorporating exogenous variables. Nonetheless, they indicate the likely trend and CO2 levels, assuming other factors remain constant (ceteris paribus).

Table 2: CO₂ Forecasts in 2100

Date	Value	SD
2100 Jan	523.7	62.8

2100 Dec	524.2	63.6

4 Present Day Point of View CO2 Emission Analysis

4.1 Modern Data pipeline for Mauna Loa CO2 data.

To gather modern CO2 emission data, we built a data pipeline to pull the latest weekly data from the Global Monitoring Laboratory. With a competent data source, we conduct exploratory data analysis (EDA) on the updated time series data from Dr. Xin Lan's study of atmospheric CO2 trends. We begin by plotting the time series of CO2 concentrations and a histogram of the annual changes.

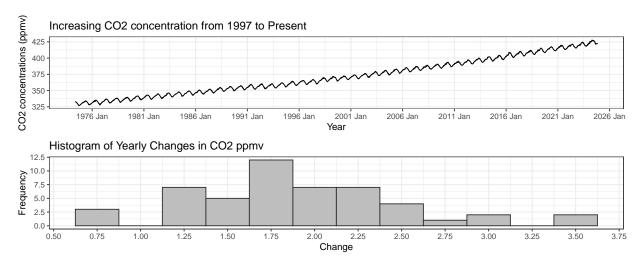

Figure 15: Data source: CO2 measurements from Mauna Loa Observatory

From 1998 to 2024, the time series continues to show a clear upward trend of global CO2 concentrations, with an average increase of 1.90 CO2 ppmv and a standard deviation of .61 CO2 ppmv. These are larger values than those calculated in 1997, indicating that the time series had a larger average increase and standard deviation from 1998 to present-day 2024. The histogram also shows a rightward shift in the distribution, indicating that the annual changes have generally increased.

We now look at the yearly ACF plot and weekly CO2 concentration to further clarify the seasonality.

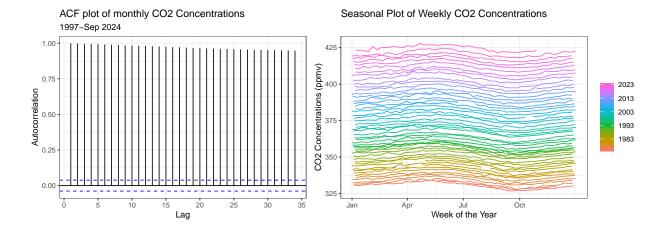

Figure 16: Observing seasonality in CO2 concentration

We see robust and persistent autocorrelation for many lags, indicating an overall trend. The time series also shows strong evidence of seasonality corresponding closely with the meteorological seasons: the seasonal plot on the right shows that CO2 concentration peaks at the start of summer and drops to a low in the fall before rising again. These observations are consistent with the 1997 report.

We now study the time series' stationarity. We conduct the Augmented Dickey-Fuller (ADF) Test to test the null hypothesis that the time series is not stationary. As seen in the time series plot for co2, we have a clear upward trend, suggesting non-stationarity. However, this is contrasted by a p-value of 0.01 yielded by the test, which indicates sufficient evidence to reject the null hypothesis of non-stationarity. To look at stationarity in variance, we fit a yearly CO2 average on the monthly time series and inspect the residuals from year to year. Although there are slight changes in the variance, they seem to regress to a constant variance over time. Thus, once we account for the yearly increases in CO2 ppmv, there is likely a constant variance over time.

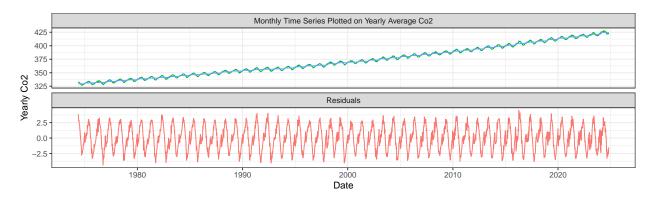

Figure 17: Studying variance over time

The new data collection method and techniques yield similar trends in average CO2 levels across months and years, with no notable deviations from prior patterns. Additionally, the residuals display consistent patterns, indicating that the updated methods align closely with previous data quality and trend behavior. The only detected change was the results of the ADF test, which found the CO2 values to be stationary.

4.2 Comparison of 1997 Polynomial (Degree 3) Model Forecasts with Actual CO2 Levels

Using observed CO2 data collected after 1997, we compare it against the forecasts from the 1997 Polynomial (Degree 3) model with the season variable to assess the model's accuracy and validate its predictions.

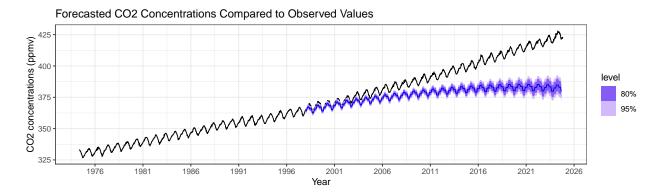

Figure 18: Forecasted with a Polynomial (3) with Season Variable Model

The plot above reveals a mismatch between the model's predictions and actual CO2 concentrations. The model had forecasted a declining trend, expecting CO2 levels to follow a curvilinear tapering, which fit well with data from the 1950s to the 1990s. However, actual concentrations continued to rise in a near-linear fashion. This tapering assumption in the Polynomial (Degree 3) model appears substantial and possibly unwarranted. Whether human-led efforts to reduce emissions or policy restrictions against such measures will be sufficient to slow this trend warrants further study and substantiation.

4.3 Comparison of 1997 ARIMA Model Forecasts with Actual CO2 Levels

We now compare the 1997 ARIMA(0,1,1)(0,1,1)[12] model's forecasts against the actual CO2 levels.

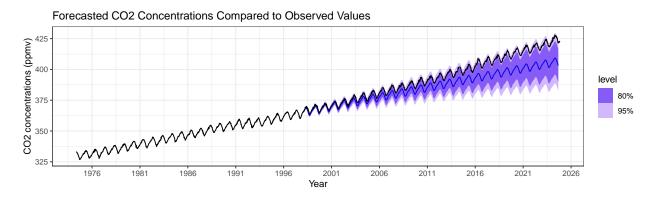

Figure 19: Forecasted with a ARIMA(0,1,1)(0,1,1)[12] Model

While more aligned with the observed trend than the curvilinear model, the ARIMA model still underestimates the rise in global CO2 concentrations. Although it captures the annual fluctuations more accurately and performs well in the short term, the forecast diverges within five years. By 2020, actual concentrations will be approximately 12.5 Co2 ppmv higher than anticipated. By 2024, observed values are barely within the tail end of the 95% confidence interval, suggesting they may soon exceed this range if current trends persist.

Table 3: Forecast Performance Comparison

Model	Mean Absolute Error (MAE)	Root Mean Squared Error (RMSE)
Polynomial (3) with Season	15.802415	19.872857
ARIMA	7.257363	8.945732

Table 4: Diebold-Mariano Test Results

Metric	Value
Test Statistic	14.3283
p-value	2.569851e-36
Interpretation	The p-value is significant, indicating the ARIMA model providing a better fit.

4.4 Evaluating the performance of 1997 Polynomial and ARIMA models

Initially, we projected that CO2 levels would reach 420 ppmv by May 2031, yet the threshold was crossed in December 2022—nearly a decade earlier, indicating a potentially more alarming trajectory for environmental impacts.

We generated a month-average series from 1997 to 2024 using weekly data to identify our forecasting error. We compared the forecasting performance of both the Polynomial (3) model with the season variable and the ARIMA model.

First, we evaluated each model's Mean Absolute Error (MAE) and Root Mean Squared Error (RMSE). The Polynomial model with seasonality exhibited a higher MAE of approximately 15.8 and an RMSE of 19.9. The ARIMA model demonstrated improved accuracy with a lower MAE of around 7.29 and an RMSE of 8.95. These results indicate that the ARIMA model better fits the data.

To formally assess the differences in forecasting accuracy, we conducted a Diebold-Mariano Test. The test returned a highly significant p-value, confirming that the ARIMA model's forecast accuracy is statistically superior to that of the Polynomial model.

4.5 Training The Best Models on Present data

4.5.1 Seasonal Adjustment

We proceed further improve on the models by seasonally adjusting the weekly data and splitting both the seasonally adjusted (SA) and non-seasonally adjusted (NSA) series into training and test sets, using the last two years (Oct 2022 - Sep 2024) as the test period. For handling 18 missing values, we apply spline interpolation, which is particularly useful as it provides a smooth curve that closely follows the trend of surrounding data points, minimizing abrupt changes and preserving the continuity of the time series. The resulting decomposition is shown in the plots below.

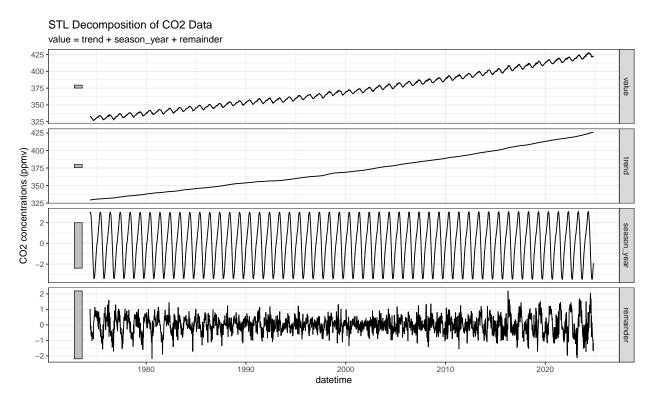

Figure 20: Clear seasonality and trend seen from decomposition

The STL decomposition reveals that CO2 levels steadily increase over time, with a stable seasonal pattern superimposed on this trend. The residuals indicate that the model effectively accounts for trend and seasonal components, leaving minimal unexplained variation.

4.5.2 ACF & PACF for Seasonally and Non-Seasonally Adjusted Data

We examine the ACF and PACF plots of the seasonally adjusted (SA) and non-seasonally adjusted (NSA) training data, differenced at lags 1 and 52 to account for the overall trend and annual seasonality. This analysis will guide our selection of appropriate ARIMA models for the data.

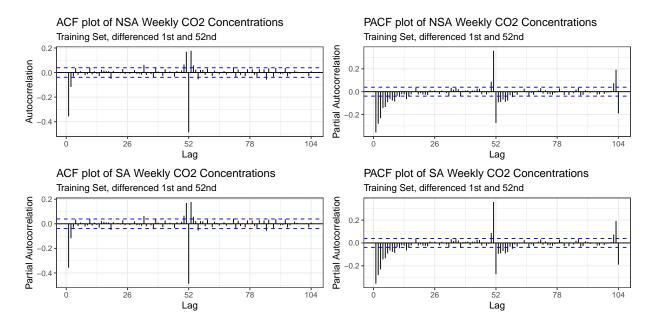

Figure 21: EDA on training and test sets

In the non-seasonally adjusted (NSA) data, the ACF displays a sharp tapering, while the PACF tapers off more gradually, suggesting that an MA model may be more suitable. Additionally, the spikes observed at the 52nd lag indicate the potential for incorporating an AR seasonal component. However, we will allow the ARIMA function to select the optimal model automatically.

For the seasonally adjusted (SA) data, which has already been de-trended, we observe a tapering ACF and a sharply dropping PACF, further simplifying the model selection. Here, we will also rely on the ARIMA function to determine the best-fitting model. The resulting model selections are shown in the tables below.

Table 5: NSA ARIMA Model Results

Model	AICc	BIC	LogLik
Auto: ARIMA $(0,1,3)(2,1,0)[52]$	3332.5	3361.537	-1661.238

Table 6: SA ARIMA Model Results

Model	AICc	BIC	LogLik
Auto: $ARIMA(4,1,1)$	2855.181	2895.969	-1420.568

We now move to assess model residuals beginning with the NSA model ARIMA(0,1,3)(2,1,0)[52]. The NSA model residuals yield the following plots.

Table 7: (#tab:ljung box test nsa)Ljung-Box Test Results on NSA Residuals

Metric	Value
Test Statistic	65.2222
Degrees of Freedom	52
p-value	1.029929e-01

Table 8: (#tab:ljung box test sa)Ljung-Box Test Results on SA Residuals

Metric	Value
Test Statistic	137.7725
Degrees of Freedom	52
p-value	1.087204e-09

4.5.3 SA and NSA Model Residuals Analysis

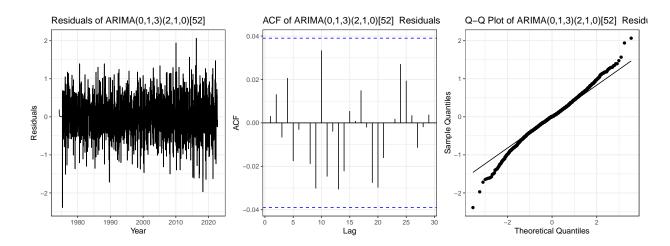

Figure 22: Evaluating ARIMA model for NSA data

The residuals largely resemble white noise, and the Q-Q plot reasonably approximates a normal distribution. The Ljung-Box Test on the residuals yields a p-value of 0.103, providing insufficient evidence to reject the null hypothesis of no autocorrelation. Thus, we find this model satisfactory. Notably, this model differs from the one trained on data only up to 1997, which may suggest underlying changes in the CO2-generating system over time. We now evaluate the residuals for the seasonally adjusted (SA) data.

The residuals for the seasonally adjusted (SA) data do not resemble white noise, and the Ljung-Box test yielded a p-value of approximately 1.087e-09, providing strong evidence to reject the null hypothesis of no autocorrelation in the residuals. We experimented with alternative models, such as ARIMA(0,1,4), based on insights from the ACF and PACF plots, but these did not yield improved results.

Despite these adjustments, we will now evaluate the forecasts from both the original and alternative models on our test data. We will compare each model's fit to the actual data and assess their forecast accuracy.

4.5.4 Comparison of Models to Actual Data

The two plots above show that the fitted values (in blue) closely align with the actual values (in black), indicating a solid fit. For the forecasts, the 95% confidence intervals (also in blue) encompass the actual data,

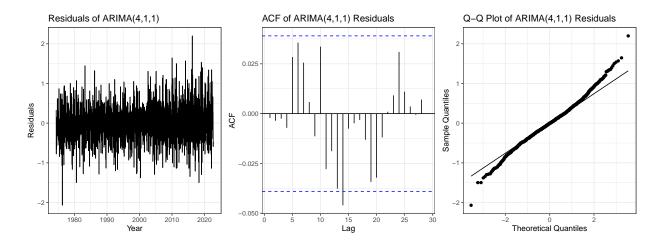

Figure 23: Evaluating ARIMA model for SA data

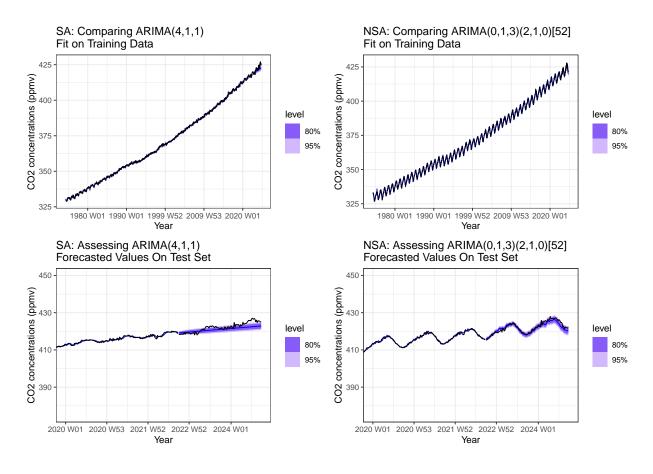

Figure 24: Assessing ARIMA Models on NSA and SA data

though the NSA model appears to provide a slightly closer fit to the observed values. We now proceed with a quantitative comparison by calculating the RMSE and MAE for each model to assess their performance more accurately.

Table 9: Comparison of NSA and SA Models on Training and Test Sets

Metric	NSA.ARIMA.Model	SA.ARIMA.Model
RMSE (Training)	0.4688655	0.4248209
MAE (Training)	0.3552181	0.3248854
RMSE (Test)	1.0349247	1.8245332
MAE (Test)	0.8330466	1.4596259

The table above shows that the SA model outperformed the NSA model on the training set in both RMSE and MAE metrics. However, on the test set, the NSA model (ARIMA(0,1,3)(2,1,0)[52]) achieved superior performance, suggesting it generalizes better. Recognizing potential for improvement in the SA ARIMA model, we now proceed to fit a polynomial time-trend model for the SA series and compare its performance with that of the SA ARIMA model.

Table 10: (#tab:assesing poly three model) RMSE and MAE for Polynomial (3) Model on Training and Test Sets

Dataset	RMSE	MAE
Training Set	0.7558251	0.6160011
Test Set	1.6112463	1.3769774

4.5.5 SA Polynomial time-trend and ARIMA model Comparison

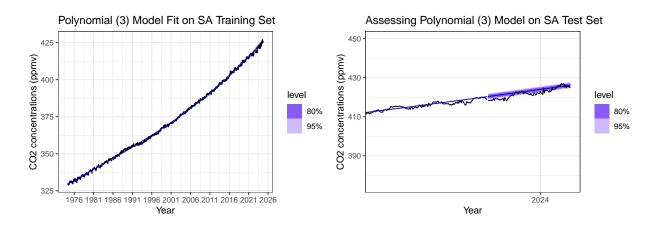

Figure 25: Assessing Polynomia (3) Model on SA data

As shown in the table above, the Polynomial (3) model fits the overall trend reasonably well, though it struggles with forecasting accuracy, as the actual data falls outside the 95% confidence interval. Notably, the Polynomial (3) model achieved an RMSE and MAE of 0.756 and 0.616 for the training set, and an RMSE and MAE of 1.61 and 1.38, respectively, for the test set. This indicates that, while the SA ARIMA model outperformed the Polynomial (3) model on the training data, the Polynomial (3) model generalized better, yielding lower RMSE and MAE values on the test set.

4.6 Pushing The Limits of Model Generalization

With the non-seasonally adjusted data series, we now generate predictions for when atmospheric CO2 is expected to be at 420 ppmv and 500 ppmv levels for the first and final times. We also generate a prediction for atmospheric CO2 levels in the year 2122.

Table 11: CO2 Levels and Forecasted Times ARIMA NSA with 80% Confidence Intervals

CO2.Level	First.Month	First.Value	Last.Month	Last.Value
420 ppmv	2022 Dec	420.1 (419.3, 421.0)	2024 Sep	420.8 (419.1, 422.5)
500 ppmv	2056 Feb	500.2 (448.5, 551.9)	2058 Aug	500.8 (443.3, 558.4)

Using the non-seasonally adjusted model, the table above presents projections for when atmospheric CO2 concentrations are anticipated to reach 420 ppmv and 500 ppmv levels, both for the first occurrence and the final plateau. This provides insights into the timeline of CO2 concentration milestones based on current trends, though it does not factor in potential mitigation efforts.

In the following table, we now forecast CO2 levels up to the year 2122, including the standard deviation. However, these projections do not account for current global initiatives to reduce greenhouse gases, such as the transition from gas-powered vehicles to electric vehicles as part of the drive toward net-zero emissions. Given that human activities and policy changes heavily influence CO2 levels, these forecasts are unlikely to be highly accurate over such a long horizon.

Table 12: CO2 Forecasts in 2122

5 Summary and Results

In this report, we explored atmospheric CO2 trends using historical data and modern forecasting techniques to assess future CO2 concentrations and evaluate model accuracy over time. Our primary goal was to determine the effectiveness of models trained on past data (up to 1997) in predicting current CO2 levels and identify the limitations and potential improvements for future projections.

5.1 Processes Undertaken

- 1. Data Collection and Cleaning We began by consolidating CO2 data from Mauna Loa, covering the period from Dr. Charles David Keeling's initial collection in 1958 to present-day data. This step ensured continuity in the data series, enhancing our model's historical context. We applied spline interpolation to address minor gaps in the data, preserving data integrity without introducing artifacts.
- 2. Exploratory Data Analysis (EDA) We visualized the time series through EDA, identifying long-term trends and seasonal patterns consistent with known CO2 behaviors, such as annual peaks in late spring and troughs in fall. The ACF and PACF plots guided us in understanding autocorrelations and seasonal cycles, crucial in constructing accurate time-series models.
- 3. Model Selection and Testing We trained Polynomial (3) models with monthly and seasonal variables and ARIMA models, with adjustments for both seasonally adjusted and non-adjusted series. The Polynomial model aimed to capture long-term trends, while ARIMA models addressed short-term and seasonal fluctuations. The goal was to find models that minimized error metrics like MAE and RMSE, making predictions that could extend from the training data to accurately fit test data.
- 4. **Residual Analysis and Model Validation** Evaluating residuals for both Polynomial and ARIMA models helped verify model fit and detect autocorrelations. Testing models against current data revealed where prior forecasts underestimated the rise in CO2 concentrations, suggesting that the simple Polynomial approach could not fully account for the underlying trend dynamics.
- 5. Forecasting Critical CO2 Levels Based on our most robust models, we forecasted critical CO2 milestones, such as the initial reach of 420 ppmv and projections for 500 ppmv, to evaluate when these levels might be exceeded. This analysis provided a timeline, illustrating potential near-future impacts on global temperatures and climate systems.

Model	RMSETrain.	MAETrain.	RMSETest.	MAETest.
1997 Polynomial (3) Model w/ Seasonality	NA	NA	19.8729	15.8024
1997 ARIMA $(0,1,1)(0,1,1)[12]$	NA	NA	8.9457	7.2574
New Polynomial (3) Model w/ Seasonality	0.7558	0.6160	1.6112	1.3770
New NSA ARIMA $(0,1,3)(2,1,0)[52]$	0.4689	0.3552	1.0349	0.8330

5.2 Results

Our analysis provided several key insights into the modeling of atmospheric CO2 trends:

- 1. Model Performance The Diebold-Mariano test confirmed the superiority of the 1997 ARIMA model over the 1997 Polynomial model, with statistically significant improvements in forecast precision. Despite these results, the 1997 models did not generalize well compared to the actual data. To rectify updated data and data collection techniques used in Mauna Loa's CO2 emissions tracker, we developed updated ARIMA and Polynomial models. The updated NSA ARIMA model (ARIMA(0,1,3)(2,1,0)[52]) outperformed all other models, including the Polynomial (3) model with seasonality, demonstrating substantially lower error metrics and a more accurate forecast on the test set. Compared to the original 1997 models, these updated models show striking advances. The test set RMSE for the updated Polynomial (3) model with seasonality dropped from 19.8729 in the 1997 version to 1.6112, a remarkable reduction of 91.9%. The updated NSA ARIMA model reduced the 1997 ARIMA's test RMSE of 8.9457 to 1.0349, marking an 88.4% improvement. The MAE improvements are equally substantial: the 1997 Polynomial model's test MAE of 15.8024 fell to 1.3770 in the updated version, a 91.3% improvement, while the updated NSA ARIMA model's test MAE of 0.8330 reflects an 88.5% enhancement over the 1997 ARIMA model's 7.2574. These impressive percentage gains highlight the updated models' enhanced accuracy and generalization capacity, with the NSA ARIMA model emerging as the most precise and reliable across various metrics and training scenarios.
- 2. Forecast Accuracy While adequate for fitting the training data, the polynomial (3) model struggled with long-term accuracy, particularly in its tendency to taper off at high CO2 levels—a behavior not observed in actual data. The ARIMA model also underestimated the rapid increase in CO2 concentrations but performed better overall, capturing more short-term variations and remaining closer to the observed values in recent years.
- 3. Significant Findings on CO2 Milestones Our projections indicate that CO2 concentrations crossed 420 ppmv in December 2022, almost a decade earlier than prior models predicted, signaling a more accelerated trajectory for emissions than anticipated. Forecasts suggest that CO2 levels could reach 500 ppmv by mid-century, with an associated rise in global temperatures and increased risk of climate tipping points.
- 4. Long-Term Projections and Limitations While the NSA ARIMA model provided reliable short-and medium-term forecasts, it may not fully capture the long-term effects of emissions policies and climate mitigation efforts. Our projections for 2122 highlight the possibility of reaching critical CO2 levels unless significant interventions reduce emissions, emphasizing the importance of incorporating exogenous variables into future models to account for policy-driven changes.

These improvements underscore the importance of regularly updating forecasting models to better account for evolving environmental patterns. The updated NSA ARIMA model's robust fit to current CO2 trends highlights the critical role of dynamic modeling in enhancing predictive accuracy for future climate projections.

5.3 Significance and Purpose of This Report

This report underscores the strengths and limitations of statistical modeling in predicting CO2 concentrations by examining historical model performance against actual outcomes. Through this comparison, we

highlighted the need for adaptable models that incorporate exogenous factors and respond effectively to rapid environmental changes. The discrepancies between previous forecasts and recent data emphasize that static models may underestimate climate trends, particularly under accelerating emissions scenarios.

Our report serves as a practical evaluation of forecasting methods, aiming to improve climate models in the context of dynamic human activity. By identifying limitations and adjusting for updated data, we seek to enhance forecasting accuracy, paving the way for more reliable climate projections. These advancements can inform policy decisions, guide mitigation strategies, and support global efforts to monitor and manage CO2 emissions effectively.
